CMPS 212—Intermediate Programming with Data Structures

Programming Assignment #8: Huffman Coding

Due date: Monday April 18,2022

This program focuses on binary trees, priority queues, maps, and input/output. Turn in files named HuffmanTree.java, HuffmanNode.java from the Homework section of the web site. You will need support files HuffMain.java, Bit*.java, and input files (provided with this HW).

Huffman Coding:

Huffman coding is an algorithm devised by David A. Huffman of MIT in 1952 for compressing text data to make a file occupy a smaller number of bytes. This relatively simple compression algorithm is powerful enough that variations of it are still used today in computer networks, fax machines, modems, HDTV, and other areas.

Normally text data is stored in a standard format of 8 bits per character, commonly using an encoding called ASCII that maps every character to a binary integer value from 0-255. The idea of Huffman coding is to abandon the rigid 8-bits-per-character requirement and use different-length binary encodings for different characters. The advantage of doing this is that if a character occurs frequently in the file, such as the letter 'e', it could be given a shorter encoding (fewer bits), making the file smaller. The tradeoff is that some characters may need to use encodings that are longer than 8 bits, but this is reserved for characters that occur infrequently, so the extra cost is worth it.

The table below compares ASCII values of various characters to possible Huffman encodings for the text of Shakespeare's *Hamlet*. Frequent characters such as space and 'e' have short encodings, while rarer ones like 'z' have longer ones.

Character	ASCII value	ASCII (binary)	Huffman (binary)
' '	32	00100000	10
'a'	97	01100001	0001
'b'	98	01100010	0111010
'c'	99	01100011	001100
'e'	101	01100101	1100
' Z '	122	01111010	00100011010

The steps involved in Huffman coding a given text source file into a destination compressed file are the following:

- 1. Examine the source file's contents and count the number of occurrences of each character.
- 2. Place each character and its frequency (count of occurrences) into a sorted "priority" queue.
- 3. Convert the contents of this priority queue into a binary tree with a particular structure.
- 4. Traverse the tree to discover the binary encodings of each character.
- 5. Re-examine the source file's contents, and for each character, output the encoded binary version of that character to the destination file.

Encoding a File:

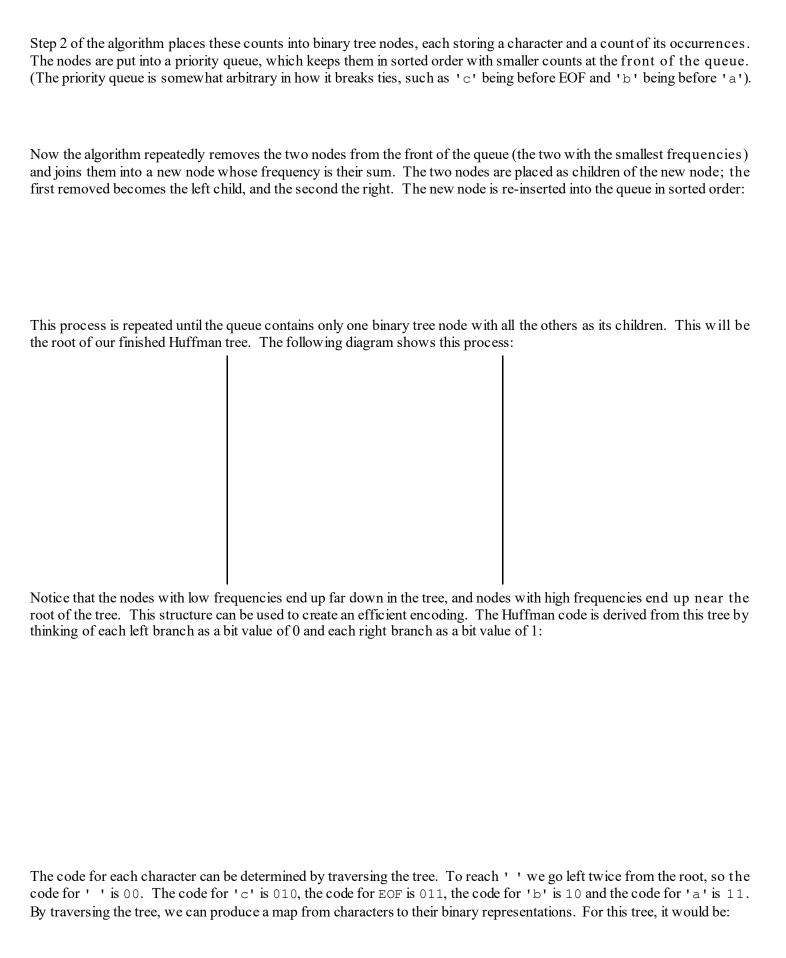

For example, suppose we have a file named example. txt with the following contents:

ab ab cab

In the original file, this text occupies 10 bytes (80 bits) of data. The 10th is a special "end-of-file" (EOF) byte.

byte	1	2	3	4	5	6	7	8	9	10
char	'a'	'b'	1 1	'a'	'b'	, ,	'c'	'a'	'b'	EOF
ASCII	97	98	32	97	98	32	99	97	98	256
binary	01100001	01100010	00100000	01100001	01100010	00100000	01100011	01100001	01100010	N/A

In Step 1 of Huffman's algorithm, a count of each character is computed. (In this assignment, our provided client program does this part for you, so you don't need to do it yourself.) The counts are represented as a map:

```
{' '=00, 'a'=11, 'b'=10, 'c'=010, EOF=011}
```

Using this map, we can encode the file into a shorter binary representation. The text ab ab cab would be encoded as:

char	'a'	'b'	' '	'a'	'b'	' '	'c'	'a'	'b'	EOF
binary	11	10	0.0	11	10	0.0	010	11	10	011

The overall encoded contents of the file are 1110001110000101110011, which is 22 bits, or almost 3 bytes, compared to the original file which was 10 bytes. (Many Huffman-encoded text files compress to about half their original size.)

byte		1	2			3		
char	a b	а	b	С	а	b	EOF	
binary	1110	0011	100	0001	01	110	001100	

Since the character encodings have different lengths, often the length of a Huffman-encoded file does not come out to an exact multiple of 8 bits. Files are stored as sequences of whole bytes, so in cases like this the remaining digits of the last bit are filled with 0s. You do not need to worry about this in the assignment; it is part of the underlying file system.

It might worry you that the characters are stored without any delimiters between them, since their encodings can be different lengths and characters can cross byte boundaries, as with 'a' at the end of the second byte above. But this will not cause problems in decoding the compressed file, because Huffman encodings have a *prefix property* where no character's encoding can ever occur as the start of another's encoding. This is important when you decode the file later.

Decoding a File:

You can use a Huffman tree to decode text that was compressed with its encodings. The decoding algorithm is to read each bit from the file, one at a time, and use this bit to traverse the Huffman tree. If the bit is a 0, you move left in the tree. If the bit is 1, you move right. You do this until you hit a leaf node. Leaf nodes represent characters, so once you reach a leaf, you output that character. For example, suppose we are asked to decode a file containing the following bits:

101101000110111011

Using the Huffman tree, we walk from the root until we find characters, then we output them and go back to the root.

First we read a 1 (right), then a 0 (left). We reach 'b' and output b. Back to the root. 1011010001101111011
We read a 1 (right), then a 1 (right). We reach 'a' and output a. 101101000110111011
We read a 0 (left), then a 1 (right), then a 0 (left). We reach 'c' and output c. 101101000110111011
We read a 0 (left), then a 0 (left). We reach 'a' and output a space. 101101000110111011
We read a 1 (right), then a 1 (right). We reach 'a' and output a. 101101000110111011
We read a 0 (left), then a 1 (right), then a 0 (left). We reach 'c' and output c. 101101000110111011
We read a 1 (right), then a 1 (right). We reach 'a' and output a. 101101000110111011

So the overall decoded text is bac aca. (The input source reports when we reach an EOF character of 011, so we stop.)

Implementation Details:

In this assignment you will create a class <code>HuffmanTree</code> to represent the overall tree of character frequencies drawn on the previous page. You will also create a class <code>HuffmanNode</code> where each node stores information about one character. The contents of the <code>HuffmanNode</code> class are up to you, but it should not perform a large share of the overall algorithm.

Your HuffmanTree class must have the following public constructor and methods:

public HuffmanTree (Map<Character, Integer> counts)

In this constructor you are passed a map from characters (char) to the number of occurrences of that character (int). You should use this map to build your Huffman tree using a priority queue (PriorityQueue) as previously described.

public Map<Character, String> createEncodings()

In this method you should traverse your Huffman tree and produce a mapping from each character in the tree to its encoded binary representation as a String. For the example shown on the previous pages, the map is the following: {' '=00, 'a'=11, 'b'=10, 'c'=010, EOF=011}

The client may want to modify the map you return, so you shouldn't return any map that you expect to remain untouched.

public void compress(InputStream input, BitOutputStream output) throws IOException

In this method you should read the text data from the given input file stream and use your Huffman encodings to write a Huffman-compressed version of this data to the given bit output file stream. You will use a BitOutputStream object to help you write the binary output one bit at a time, as described below.

public void decompress (BitInputStream input, OutputStream output) throws IOException

In this method you should read the compressed binary data from the given bit input file stream and use your Huffman tree to write a decompressed text version of this data to the given output file stream. You may assume that all characters in the input file were represented in the map of counts passed to your tree's constructor. You will use a BitInputStream object to help you read the binary input one bit at a time, as described below.

You may have additional methods, so long as they are private. Note that the methods might be called in any order.

If a parameter passed to any method above is null, you should throw an IllegalArgumentException. If your object is asked to compress/decompress an empty file, the result should also be an empty file. Methods that traverse your tree should be implemented recursively whenever practical.

Your classes will interact with a provided HuffMain client program that prompts the user for a file name to compress. When compressing a file, the HuffMain program also saves a separate file with a .count extension that stores the counts of every character in the original file. This is so that the HuffmanTree can be reconstructed later when decompressing.

BitOutputStream and BitInputStream:

To compress/decompress files, you will want to read and write binary data one bit at a time. Java's built-in input/output streams read an entire byte at a time, which makes it difficult to examine each bit. Therefore we are providing you with BitOutputStream and BitInputStream classes with writeBit and readBit methods to make it easier. Every constructor and method of these classes throws IOException if something fails during the input/output process.

BitOutputStream Method	Description
<pre>public void writeBit(int bit)</pre>	writes a single 0 or 1 bit to the output
<pre>public void writeBits(String bits)</pre>	treats each character of the given string as a bit ('0' or '1') and writes each of those bits to the output
public void close ()	stops writing (important to call this to ensure data is saved)
±	7
BitInputStream Method	Description
	Description reads a single 0 or 1 bit from input; returns -1 at end of file
BitInputStream Method	

Development Strategy and Hints:

We suggest that you first focus on building your Huffman tree properly from the given map of character counts. Then work on creating the map of char \rightarrow String encodings from your tree. Then work on using your encodings to compress files, and lastly work on trying to decompress a file that you have previously compressed.

For your nodes to be able to be stored in a priority queue, the queue needs to know how to sort them. Therefore your node class must implement the Comparable interface as discussed in lecture and section. Nodes should be compared by character frequency, where a character that occurs fewer times is "less than" one that occurs more often. If two nodes have the same number of occurrences, they are considered "equal" in this context.

Consider writing a toString method in your HuffmanNode so you can easily print nodes or priority queues of them. Note that if you println a priority queue, it does not necessarily show its elements in the order they would be returned.

It can be difficult to tell whether you have compressed/decompressed a file correctly. If you open a Huffman-compressed binary file in a text editor, the appearance will be gibberish (because the text editor will try to interpret the bytes as ASCII encodings, which is not the way the data is stored). While developing your program, it can be helpful to write out each 0 or 1 as an entire character (byte) rather than as a bit. This defeats the purpose of compression, because the "compressed" file is actually larger than the original, but it can help you see whether the 0s and 1s are what you expect.

Our BitOutputStream and BitInputStream extend Java's OutputStream and InputStream classes respectively. To write out your 0s and 1s as entire bytes instead of as bits, you can simply call the bit output stream's write method (which writes a byte, as with any other output stream) rather than its writeBit method. There is also a writeBytes method that takes a String, to replace the writeBits method. Alternatively, you can switch your bit input/output stream from "bit mode" into "byte mode" so that every read/writeBit call actually reads/writes an entire byte. Do so by calling the setBitMode method on the stream with a parameter of false. For example:

bitOut.setBitMode(false); // writes data as bytes, rather than bits (for debugging)

The provided HuffMain client program can compress any text file. We suggest you start with a very small input file such as the example shown in this document, and work your way up to larger files once that works.

Style Guidelines and Grading:

Part of your grade will come from appropriately utilizing binary trees and recursion to implement your Huffman tree as described previously. We will also grade on the elegance of your recursive algorithms; don't create special cases in your recursive code if they are not necessary or repeat cases already handled. Redundancy is another major grading focus; some methods are similar in behavior or based off of each other's behavior. You should avoid repeated logic as much as possible. Your class may have other methods besides those specified, but any other methods you add should be private.

You should follow good general style guidelines such as: making fields private and avoiding unnecessary fields; declaring collection variables using interface types; appropriately using control structures like loops and if/else; properly using indentation, good variable names and types; and not having any lines of code longer than 100 characters.

Comment your code descriptively in your own words at the top of your class, each method, and on complex sections of your code. Comments should explain each method's behavior, parameters, return, pre/post-conditions, and exceptions. For reference, our HuffManTree class is around 125 lines long (60 "substantive") including comments and blank lines.
